

then, as Crofton first made perfectly clear (Phil. Trans. that curve must be either the ordinary probability-curve or a distortion of it which still leaves it with a single maximum. In my memoir 'On the Theory of Errors of Observations' (U.S. Coast Survey Report, for 1877, p. 200) will be found a plate giving twenty-four curves each drawn from five hundred cases, which give one an idea of how much variation from the theoretical curve can be expected. But now turn to the admirable examination by Mr. Flinders Petrie of the weights found in Nauvratia (Third Mem. of Egyptian Exploration Fund, Part I, pp. 69 et seq. with Plate xxiv.) Here we find, especially in regard to Egyptian weights of from 9 to $9\frac{3}{4}$ grammes, perfectly unmistakable evidence of two maxima, showing that the weights ~~then~~ ^{indirect} were copies of two prototypes at least, and therefore belong to at least two different classes, and yet they ~~have some of them~~ ^{are} all in intermediate weights. Therefore, the mere fact of the existence of intermediate forms does not prove that the division
